### Abstract

The aqueous colloidal processing of submicrometre B<sub>4</sub>C powder (~0.6 μm) with coarse Ti-Al powder (~40 μm) as sintering additive was investigated. Firstly, by measuring the zeta potential, pHs were identified that promote the individual colloidal stability of the B<sub>4</sub>C and Ti-Al particles as well as their co-dispersion in water with two different deflocculants (one anionic and the other cationic). It was found that the anionic and cationic deflocculants shift the isoelectric points of B<sub>4</sub>C and Ti-Al to more acidic and more basic pHs, respectively, making their co-dispersion possible at neutral pH. And secondly, by means of rheological studies, conditions were identified (sonication time, deflocculant type, and deflocculant content) that at quasi-neutral pH yield B<sub>4</sub>C+Ti-Al shear-thinning concentrated suspensions (30 vol.% total solids) with low viscosity and small hysteresis loop. Interestingly, those deflocculated with the cationic polyelectrolyte had better rheological behaviour, being also less viscous and almost non-thixotropic. These suspensions were freeze-dried, obtaining powder mixtures that were compacted by conventional spark plasma sintering (SPS), and also slip-cast, obtaining robust

## 1. Introduction

The great demand for ever harder ceramic parts for structural applications has led to soaring interest in the processing of advanced ceramics and composites based on  $B_4C$ , the third hardest compound known to man (after diamond and cubic BN) and the hardest compound synthesized routinely on a large scale (in tonnes) [1-3]. In addition,  $B_4C$  is not only superhard, but also ultra-lightweight and very refractory [1,3]. It excels in ballistic performance, and is indeed the reference material for the fabrication of personnel and vehicle armours [1-8]. It also stands out in wear resistance, and thus is a very appealing material for the manufacture of tribocomponents [1,2,9-15].

A common feature in these applications is the need for geometrically-complex parts produced by near-net-shape manufacturing techniques because the operations of diamond machining and finishing of densely-sintered  $B_4C$  parts are prohibitively expensive and time-consuming, if not to say inviable. Thus for example, the large front/back plates and the small side plates of body armour systems are relatively flat, so that they can be near-net-shape manufactured from dry ceramic powders by hot-pressing [6]. This is also the case for the chassis or fuselage panels of the vehicle armour systems. Other items of body armour systems, such as deltoids, shin pads, knee pads, helmets, etc., have ergonomic designs with large curvatures, and hence can be near-net-shape manufactured from colloidal ceramic suspensions by casting techniques (slip-casting, gel-casting, freeze casting, etc.) or from ceramic pastes by plastic forming processes (extrusion, injection molding, etc.), in both cases followed by pressureless sintering of the green bodies [6]. This is also the case of other items of vehicle armour systems such as nose-cone and wing/fin protections. Ceramic tribocomponents for wear applications have custom designs with specific requirements of size and geometry, and are fabricated using

1  
2  
3  
4 different near-net-shape manufacturing techniques depending on their particular degree of shape  
5  
6 complexity.  
7

8  
9         Fabricating dense B<sub>4</sub>C parts is, however, very challenging in practice. This is due to the  
10 poor sinterability of B<sub>4</sub>C [2], whose densification is intrinsically limited by the strong covalent  
11 nature of its bonding and its low self-diffusion coefficients [2,16] – a combination that imposes  
12 serious kinetics restrictions. It is for these reasons that densification of B<sub>4</sub>C requires sintering  
13 cycles at very high temperatures ( $\geq 2200^{\circ}\text{C}$ ) for very prolonged times (a few hours) [2].  
14 However, even this does not completely solve the problem because the oxidic impurities (i.e.,  
15 H<sub>3</sub>BO<sub>3</sub> or B<sub>2</sub>O<sub>3</sub>) typically present in B<sub>4</sub>C promote mass transport by surface diffusion and  
16 evaporation-condensation during the slow heating ramps applied by the conventional furnaces  
17 and hot-presses, and this favours coarsening over densification [16-19]. Consequently, sintering  
18 of B<sub>4</sub>C is very problematic both intrinsically and extrinsically. Spark plasma sintering (SPS) uses  
19 ultra-fast sintering cycles [20,21], thus minimizing the exposure times to those temperatures at  
20 which coarsening is favoured over densification. SPS with pressure could then be used instead of  
21 hot-pressing in making B<sub>4</sub>C parts with little curvature (i.e., geometrically simple parts) from dry  
22 powders, whereas pressureless SPS could replace conventional pressureless sintering in  
23 fabricating B<sub>4</sub>C parts with large curvature (i.e., geometrically complex parts) from cast green  
24 bodies. Moreover, SPS could be used in combination with transient liquid-phase sintering  
25 additives to fabricate B<sub>4</sub>C parts at smoother sintering conditions, without intergranular residual  
26 phases [22-25].

52  
53         The present work was thus aimed at studying the aqueous colloidal processing of  
54 submicrometre B<sub>4</sub>C with its coarse Ti-Al transient liquid-phase sintering additive, addressing the  
55 environmentally friendly preparation in water of both powder mixtures by freeze-drying and

3  
4 complex-shape green bodies by slip-casting that could be densified by SPS (the former with  
5 pressure, and the latter without pressure). The aqueous colloidal processing of B<sub>4</sub>C is indeed very  
6  
7 challenging due to the innate difficulty in preparing low-viscosity concentrated suspensions of  
8  
9 B<sub>4</sub>C in water [26], and therefore this will be the central focus of the present study which is  
10  
11 mostly devoted to processing and shaping aspects. The colloidal processing of B<sub>4</sub>C in water has  
12  
13 not been yet studied in detail, although there are some papers devoted to the dispersion of B<sub>4</sub>C  
14  
15 powders in order to prepare concentrated suspensions for the manufacture of bulk complex  
16  
17 shaped parts by slip casting or gelcasting and even of laminated materials by tape casting. In  
18  
19 those studies, several deflocculants have been used, such as ammonium polyacrylate salts [27],  
20  
21 tetramethylammonium hydroxide [28,29], and polyethyleneimine [30,31]. Nonetheless,  
22  
23 preliminary SPS results will also be presented as a complement to the study of the aqueous  
24  
25 colloidal processing, which represent only a first demonstration of the densificability of both the  
26  
27 powder mixtures and green bodies so-prepared.

## 38 **2. Experimental Procedure**

39  
40 The starting materials were commercially available submicrometre B<sub>4</sub>C (Grade HD 20,  
41  
42 H.C. Starck, Germany) and micrometre Ti-Al (Alfa Aesar, Germany) powders. According to the  
43  
44 manufacturers' specifications, the B<sub>4</sub>C and Ti-Al powders have purities of >99 and >99.8%,  
45  
46 respectively. In addition, characterization performed by laser scattering and He  
47  
48 stereopycnometry indicated that the B<sub>4</sub>C powder has a mean particle size of ~0.7 μm and an  
49  
50 absolute density of ~2.559 g/cm<sup>3</sup>, and that the corresponding values for the Ti-Al powder are ~38  
51  
52 μm and ~3.841 g/cm<sup>3</sup>. The coarse Ti-Al particles are actually agglomerates of submicrometre  
53  
54 primary particles of γ-TiAl (major phase), α<sub>2</sub>-Ti<sub>3</sub>Al (minor phase), and TiAl<sub>2</sub> (minor phase). The

62  
63  
64  
65

1  
2  
3  
4 B<sub>4</sub>C and Ti-Al powders were also characterized by X-ray photoemission spectroscopy (XPS; K-  
5  
6 Alpha, Thermo Scientific, UK), to thus examine the state of the particle surface. The procedure  
7  
8 of aqueous colloidal processing of powders and suspensions of B<sub>4</sub>C+Ti-Al followed the standard  
9  
10 protocol, as will be described next.  
11  
12

13  
14 At a first stage, the colloidal stability of the B<sub>4</sub>C and Ti-Al powders was studied  
15  
16 individually using dilute suspensions (0.1 g/l) with a short equilibrium time (< 10 min). To this  
17  
18 end, systematic zeta potential measurements were made (Zetasizer Nano-ZS, Malvern, UK) as a  
19  
20 function of pH – adjusted in the acidic or basic ranges using HCl or KOH solutions (1, 10<sup>-1</sup>, or  
21  
22 10<sup>-2</sup> M), respectively – on suspensions prepared using deionized water as suspension medium  
23  
24 plus KCl 10<sup>-2</sup> M as inert electrolyte, and sonicated for 1 min. The zeta potential measurements  
25  
26 were made both without and with deflocculant addition. Specifically, two different commercially  
27  
28 available polyelectrolytes were used as possible deflocculants. One is a cationic  
29  
30 polyethylenimine (PEI; M<sub>w</sub> ~25000; Sigma-Aldrich, USA), and the other is an anionic  
31  
32 ammonium salt of polyacrylic acid (PAA; Duramax<sup>TM</sup> D-3005, Rohm & Hams, USA). Next, at a  
33  
34 second stage, concentrated suspensions with composition 95 vol.%B<sub>4</sub>C+5 vol.%Ti-Al were  
35  
36 prepared to a total solids loading of 30 vol.%, at a certain pH. The concentrated suspensions  
37  
38 were prepared under continuous mechanical stirring with helices, using the following protocol of  
39  
40 sequential addition. First, the desired total amount of deflocculant was incorporated into the de-  
41  
42 ionized water (70 vol.%), followed by agitation for 5 min and sonication for 1 min. Next, the Ti-  
43  
44 Al powder was added, followed by agitation for 5 min. Then, the B<sub>4</sub>C powder was added  
45  
46 gradually, after which the pH was adjusted from the natural pH to the desired value.  
47  
48  
49  
50  
51  
52  
53  
54

55 The resulting B<sub>4</sub>C+5 vol.%Ti-Al concentrated suspensions were stirred for 30 min and  
56  
57 then characterized rheologically in their as-prepared condition, and also after sonication for  
58  
59  
60  
61  
62  
63  
64  
65

1  
2  
3  
4 different times in a min-by-min sequence with stirring for 5 min. The rheological behaviour of  
5  
6 the suspensions was evaluated using a rheometer (MARS, Haake, Thermo, Germany) operated in  
7  
8 controlled shear rate mode. The rheometer was configured in the double cone (cone angle of 2°)-  
9  
10 plate geometry, and the measurement cycle of the flow curves involved a linear stretch of shear  
11  
12 rate increase from 0 to 1000 s<sup>-1</sup> in 300 s, then a plateau at 1000 s<sup>-1</sup> for 60 s, and lastly a linear  
13  
14 decrease to zero shear rate also in 300 s. The thixotropy/rheopexy was determined from the area  
15  
16 of the flow curve's hysteresis loop, and the viscosity by direct reading at 100 and 1000 s<sup>-1</sup> in the  
17  
18 uploading stretch.  
19  
20  
21  
22

23  
24 The B<sub>4</sub>C+5 vol.%Ti-Al concentrated suspension with the best rheological behaviour was  
25  
26 then selected to prepare both powders and green bodies. To obtain the powders, the suspension  
27  
28 was placed in a rotary evaporator (RV10 basic, IKA, Germany) immersed in a liquid-N<sub>2</sub> bath,  
29  
30 and once frozen was freeze-dried (Cryodos-50, Telstar, Spain) at -50°C and 0.3 mPa for 24 h. To  
31  
32 obtain the green bodies, the suspension was slip-cast in bottomless plastic moulds (greased with  
33  
34 wax) of different morphology placed on top of a flat plaster-of-Paris plate, and then was allowed  
35  
36 to dry in air at room temperature for 48 h within the moulds. The relative density of air-dried  
37  
38 green bodies was determined by Hg intrusion porosimetry (PoreMaster 60, Quantachrome  
39  
40 Instruments, UK), and the microstructure was examined by scanning electron microscopy (SEM;  
41  
42 3600N, Hitachi, Japan).  
43  
44  
45  
46  
47

48  
49 Lastly, both the B<sub>4</sub>C+5 vol.%Ti-Al powders and green bodies were densified by SPS  
50  
51 (HP-D-10, FCT Systeme GmbH, Germany), the former with pressure and the latter without  
52  
53 pressure. In particular, the powders were loaded into graphite dies (2-cm diameter) lined with  
54  
55 graphite foil and covered by graphite blankets, and were SPS-ed in dynamic vacuum at 1900°C  
56  
57 (as measured using an axial optical pyrometer), under 100°C/min heating, for 30 min under 75  
58  
59  
60  
61  
62  
63  
64  
65

1  
2  
3  
4 MPa pressure. The green bodies, however, were loaded into special graphite dies designed to  
5  
6 avoid load application and also lined with graphite foil and covered by graphite blankets, and  
7  
8 were pressureless SPS-ed in dynamic vacuum at 1900°C (as measured using an axial optical  
9  
10 pyrometer), under 100°C/min heating, for 60 min. Note that the SPS cycles with and without  
11  
12 pressure are not optimized, and are therefore aimed at showing the potential densificability of  
13  
14 both the powder mixtures and green bodies prepared here by aqueous colloidal processing. The  
15  
16 resulting B<sub>4</sub>C composites were ground and polished to a 1-μm finish using conventional  
17  
18 ceramographic methods to evaluate their hardness by Vickers indentation tests (MV-1,  
19  
20 Matsuzawa, Japan) at 9.8 N load. The B<sub>4</sub>C composites were also intentionally broken, and the  
21  
22 resulting fracture surfaces were observed by SEM (Quanta 3D, FEI, The Netherlands) to  
23  
24 discriminate on the presence or absence of residual porosity. The B<sub>4</sub>C composite fabricated by  
25  
26 SPS with pressure was also characterized by X-ray diffractometry (XRD; D8 Advance, Bruker  
27  
28 AXS, Germany), to identify the phases present.

35  
36  
37

### 38 **3. Results and Discussion**

39  
40 The first step for the aqueous colloidal processing of B<sub>4</sub>C+Ti-Al is to study the colloidal  
41  
42 stability in water of both B<sub>4</sub>C and Ti-Al so as to determine the appropriate conditions for their  
43  
44 durable co-dispersion. In this context, Fig. 1 shows the evolution of the zeta potential as a  
45  
46 function of pH for the individual dilute suspensions of B<sub>4</sub>C and Ti-Al both without and with  
47  
48 deflocculant (PEI or PAA). It can be seen that B<sub>4</sub>C shows a zeta potential curve that varies  
49  
50 smoothly with pH (i.e., with little slope and low absolute values), with its isoelectric point being  
51  
52 located at pH~5.3. At lower or greater pHs, the zeta potential increases gradually in magnitude,  
53  
54 reaching a value of 30 mV at pH~0.5 (estimate made by extrapolation) and of -30 mV at pH~9.5  
55  
56 (direct experimental measurement). At neutral pH, B<sub>4</sub>C has a zeta potential of only -13 mV. The  
57  
58  
59  
60  
61  
62  
63  
64  
65

1  
2  
3  
4 isoelectric point at pH~5.3 indicates that the surface of B<sub>4</sub>C particles is either passivated with  
5  
6 H<sub>3</sub>BO<sub>3</sub> or enriched in free carbon [26,32-34]. Indeed, the latter seems to be the likely explanation  
7  
8 according to the XPS analysis (B 1s and C 1s core-levels) of the B<sub>4</sub>C powder shown in Fig. 2,  
9  
10 which indicates that the contribution of B-O bonds to the B 1s signal is very weak, whereas that  
11  
12 of C-C bonds to the C 1s signal is very intense. Furthermore, an additional confirmation is that  
13  
14 the isoelectric point of this B<sub>4</sub>C powder is the same (pH~5.3) as that of a SiC nanopowder  
15  
16 formed by SiC nanoparticles with surface enriched in carbon [35-38]. It can also be seen in Fig.  
17  
18 1 that the addition of only 1 wt.% PEI has two important effects on the zeta potential of B<sub>4</sub>C.  
19  
20 First, it markedly shifts the isoelectric point to higher pH, in particular to pH~10.5. This is  
21  
22 because PEI is a cationic polyelectrolyte that positively charges the surface of the B<sub>4</sub>C particles.  
23  
24 And second, it notably increases the magnitude of the zeta potential both below and above the  
25  
26 isoelectric point, clear evidence for electrosteric stabilization. Indeed, the zeta potential reaches  
27  
28 values as high as 50 mV below the isoelectric point for pHs≤8.5 (thus including neutral pH). The  
29  
30 addition of PAA has similar effects in the sense that it also shifts the isoelectric point and  
31  
32 increases the magnitude of the zeta potential both below and above the isoelectric point, thus  
33  
34 providing electrosteric stabilization as well. Nonetheless, unlike PEI, 0.5 wt.% PAA (i) shifts the  
35  
36 isoelectric point to lower pH, in particular to pH~3.7, because it is an anionic polyelectrolyte that  
37  
38 negatively charges the surface of the B<sub>4</sub>C particles, and (ii) produces zeta potential values as high  
39  
40 (in magnitude) as -40 mV above the isoelectric point for pHs≥5 (thus including neutral pH too).  
41  
42  
43  
44  
45  
46  
47  
48  
49

50 Fig. 1 shows that the colloidal behaviour of the Ti-Al powder is qualitatively similar to  
51  
52 that described for the B<sub>4</sub>C powder, and therefore will be analysed more concisely. First, Ti-Al  
53  
54 also exhibits a smooth zeta potential curve with low slope, with its isoelectric point being located  
55  
56 at pH~4. This is essentially the isoelectric point of weakly acidic solids [39], which suggests that  
57  
58  
59  
60  
61  
62  
63  
64  
65

1  
2  
3  
4 the Ti-Al particles are passivated with an oxide surface. Certainly, the XPS analysis (Ti 2p and  
5 Al 2p core-levels) shown in Fig. 3 confirms this surface passivation because the contributions of  
6  
7 Ti-O-Al-O bonds to the Ti-Al 2 p signals, respectively, are markedly more intense than the  
8  
9 contributions of metallic Ti-Al. Second, the zeta potential also increases gradually in magnitude  
10  
11 for pHs below or above the isoelectric point, reaching a value of 30 mV at  $\text{pH} < 1$  (estimate made  
12  
13 by extrapolation) and of -40 mV at  $\text{pH} \geq 7.5$  (direct experimental measurement). At neutral pH,  
14  
15 Ti-Al has a zeta potential of about -33 mV. And third, the addition of PEI or PAA also provides  
16  
17 electrosteric stabilization. Thus, with 1 wt.% PEI the isoelectric point shifts to  $\text{pH} \sim 10.7$ , and the  
18  
19 zeta potential reaches values as high as 45-50 mV below the isoelectric point for  $\text{pHs} \leq 8$  (thus  
20  
21 including neutral pH). With 0.5 wt.% PAA, however, the isoelectric point shifts to  $\text{pH} \sim 3$ , and the  
22  
23 zeta potential reaches values as high as -40 mV above the isoelectric point for  $\text{pHs} \geq 6$  (thus  
24  
25 including neutral pH too).  
26  
27  
28  
29  
30  
31  
32

33 The above results indicate that in principle there are two possible ways of preparing well-  
34  
35 dispersed concentrated suspensions of  $\text{B}_4\text{C} + \text{Ti-Al}$  when one considers (i) that  $\text{B}_4\text{C}$  has  
36  
37 necessarily to be deflocculated to avoid its agglomeration and to ensure the suspension's  
38  
39 processability because it is the major solid component, (ii) that both  $\text{B}_4\text{C}$  and Ti-Al must have  
40  
41 high absolute zeta potentials (i.e., at least 30 mV) with the same sign of surface charge to ensure  
42  
43 their appropriate co-dispersion and colloidal stability, and (iii) that working with very acidic or  
44  
45 basic pHs is not at all recommendable (due to health and safety concerns). With these restraints  
46  
47 in mind,  $\text{B}_4\text{C} + \text{Ti-Al}$  suspensions can potentially be prepared in a wide range of pHs (from acidic  
48  
49 to basic pHs) using as deflocculant (i) PEI together with  $\text{pHs} \leq 9$  to ensure positive zeta potentials  
50  
51 of at least 30 mV, or (ii) PAA together with  $\text{pHs} \geq 5$  to ensure negative zeta potentials of at least -  
52  
53 30 mV. Importantly, in both cases it is possible to work with water at neutral and quasi-neutral  
54  
55  
56  
57  
58  
59  
60  
61  
62  
63  
64  
65

1  
2  
3  
4 pHs, which is very positive in terms of industrial scalability (which entails the preparation,  
5  
6 handling, and storage of large suspension volumes, and the subsequent elimination of the  
7  
8 corresponding liquid medium). The rheological studies of concentrated B<sub>4</sub>C+Ti-Al suspensions  
9  
10 will now help to elucidate which of the two deflocculants (PEI or PAA) is more recommendable,  
11  
12 in addition to other appropriate preparation conditions (i.e., deflocculant content and sonication  
13  
14 time).

15  
16  
17  
18  
19 To this end, concentrated suspensions of B<sub>4</sub>C+5 vol.%Ti-Al were prepared as described  
20  
21 in the experimental section at quasi-neutral pH to a total solids loading of 30 vol.% using as  
22  
23 deflocculant 2 or 4 wt.% PEI or PAA. Note that the use of greater proportions of deflocculant in  
24  
25 the multi-component concentrated suspensions in relation to the individual dilute suspensions is  
26  
27 simply because in the former there is much more interaction between the particles, and therefore  
28  
29 they are more prone to agglomeration. Interestingly, during the preparation of the concentrated  
30  
31 suspensions it was observed that those formulated with PAA were less dispersible and much  
32  
33 more viscous than those formulated with PEI, which already indicated that deflocculation with  
34  
35 PEI is in principle more effective and therefore more recommendable. Indeed, as can be seen in  
36  
37 Fig. 4, in terms of consistency, deflocculation with PAA actually led to pastes rather than  
38  
39 suspensions. This behaviour as a paste will not prevent its use in plastic forming operations, but  
40  
41 it is certainly undesirable in slurry shaping operations due to the poorer pouring and mould-  
42  
43 filling performances. Fig. 5 shows the flow curves of these four B<sub>4</sub>C+5 vol.%Ti-Al suspensions  
44  
45 in their as-prepared condition (i.e., without sonication), measured to confirm the aforementioned  
46  
47 visual observations. It can be seen that the suspensions prepared with PAA exhibit a very shear-  
48  
49 thinning rheological behaviour (i.e., a plastic behaviour with a relatively high yield stress), while  
50  
51 those prepared with PEI show a slightly shear-thinning rheological behaviour (i.e., pseudo-  
52  
53  
54  
55  
56  
57  
58  
59  
60  
61  
62  
63  
64  
65

1  
2  
3  
4 plastic behaviour, without a yield point). This is indeed the flow response desirable for the wet  
5  
6 shaping of green ceramic parts because the higher suspension viscosity under rest conditions  
7  
8 avoids settling, thus ensuring proper storage, whereas the lower suspension viscosity under  
9  
10 manufacturing conditions facilitates the forming of green pieces [40]. It can also be seen that the  
11  
12 suspensions prepared with PAA are (i) much more viscous (i.e., viscosities slightly greater than 1  
13  
14 Pa·s at 100 s<sup>-1</sup> and of 130-140 mPa·s at 1000 s<sup>-1</sup>), and (ii) markedly more thixotropic/rheopexic  
15  
16 (hysteresis loops of 15500-56000 Pa·s<sup>-1</sup>) than their counterparts prepared with PEI (which have  
17  
18 viscosities of 36-46 and 16-24 mPa·s at 100 and 1000 s<sup>-1</sup>, respectively, and hysteresis loops of  
19  
20 10-1900 Pa·s<sup>-1</sup>). This confirms quantitatively that deflocculation of the B<sub>4</sub>C+5 vol.%Ti-Al  
21  
22 suspensions with PEI is much more efficient, and therefore much more advisable. In addition, it  
23  
24 is clear that the B<sub>4</sub>C+5 vol.%Ti-Al suspensions prepared with PAA are too viscous (more than 1  
25  
26 Pa·s at 100 s<sup>-1</sup>) to be poured appropriately, and therefore are not at all suitable for casting  
27  
28 operations [26]. This is also the case for the aqueous suspensions of B<sub>4</sub>C prepared using as  
29  
30 deflocculant an anionic ammonium salt of polymethacrylic acid (i.e., Darvan C-N) or an  
31  
32 ethanolaminic salt of citric acid (i.e., Dolapix CE 64) [26]. On the contrary, the B<sub>4</sub>C+5 vol.%Ti-  
33  
34 Al suspensions prepared with PEI are well suited to casting operations.  
35  
36  
37  
38  
39  
40  
41  
42

43 Fig. 6 shows the flow curves of the B<sub>4</sub>C+5 vol.%Ti-Al concentrated suspensions  
44  
45 (30 vol.% of total solids) deflocculated with 2 or 4 wt.% PEI as a function of sonication time,  
46  
47 measured to identify which preparation conditions are more appropriate. It can be seen that they  
48  
49 all exhibit the desirable shear-thinning rheological behaviour, with almost no  
50  
51 thixotropy/rheopexy when sonicated. However, those prepared with 2 wt.% PEI are, for the same  
52  
53 given sonication time, less viscous, which is a very desirable attribute. This indicates that there is  
54  
55 a certain upper limit for the adsorption of PEI onto the surface of the B<sub>4</sub>C and Ti-Al particles,  
56  
57  
58  
59  
60  
61  
62  
63  
64  
65

1  
2  
3  
4 above which the excess of PEI stays in the water, increasing its viscosity, and thereby also the  
5  
6 viscosity of the resulting suspensions. In addition, the sonicated suspensions prepared with 2  
7  
8 wt.% PEI are less time-dependent (i.e., less thixotropic/rheopexic), which is another important  
9  
10 attribute because they are less prone to the formation/destruction of structures during the flow  
11  
12 cycles. Finally, it can also be seen in Fig. 6 that the viscosity of the suspensions prepared with 2  
13  
14 or 4 wt.% PEI first decreases with increasing sonication time up to a certain time, after which the  
15  
16 suspension viscosity increases if further sonicated. This simply reflects the excess sonication  
17  
18 causing some re-agglomeration because the heat-induced surface activation starts to predominate  
19  
20 over the dispersion. The optimal sonication times of the suspensions prepared with 2 and 4 wt.%  
21  
22 PEI are 3 and 1 min, respectively. The former, however, is less viscous and less time-dependent  
23  
24 than the latter, and therefore was the concentrated suspension chosen for freeze-drying and slip-  
25  
26 casting.  
27  
28  
29  
30  
31  
32

33  
34 Fig. 7 shows optical photographs of some green pieces obtained by slip-casting from the  
35  
36 optimal  $B_4C+5 \text{ vol.\%Ti-Al}$  concentrated suspension, once dried in air at room temperature for 48  
37  
38 h. These images confirm the feasibility of using the present colloidal processing route for the  
39  
40 near-net shaping of  $B_4C+Ti-Al$  green parts with complex geometries, as dictated simply by the  
41  
42 mould used. In addition, the green bodies so-prepared are robust, and have good handling and  
43  
44 storage characteristics. Fig. 8 shows SEM images of the fracture surface of these compacts in  
45  
46 their as-cast condition. It can be seen that the green compacts have a uniform microstructure,  
47  
48 with a good packing of particles, and without cracks, macrodefects, or density gradients. Also  
49  
50 importantly, the as-cast pieces have a relative density (measured by Hg intrusion porosimetry) of  
51  
52  $\sim 60.5\%$  (absolute density of  $\sim 1.59 \text{ g/cm}^3$ ), which is very high given that these compacts were  
53  
54 shaped without the help of external pressure and that the limit for the random packing density of  
55  
56  
57  
58  
59  
60  
61  
62  
63  
64  
65

1  
2  
3  
4 monosized spherical particles is 64% (which nonetheless is not the present case) [41]. Indeed,  
5  
6 these compacts are denser than others of B<sub>4</sub>C-Ni (~59.1%) [42] and B<sub>4</sub>C-Co (~58%) [24]  
7  
8 prepared for a similar total solids load by aqueous slip-casting with different deflocculants, and  
9  
10 are also denser than or equally dense as B<sub>4</sub>C compacts prepared by non-aqueous (i.e., solutions  
11  
12 of dodecane and Hypermer A70 dispersant) slip-casting using solid loads of 40 (~56.9%) and  
13  
14 45 vol.% (~60.5%) [26].  
15  
16  
17  
18

19         Interestingly, it can also be seen in Fig. 8 that the microstructure of the as-cast pieces  
20  
21 contains Ti-Al particles whose size is much smaller than the ~40 μm of the Ti-Al starting  
22  
23 powder. This suggests that the effective dispersion in water and the sonication applied during the  
24  
25 colloidal processing broke the coarse Ti-Al starting particles, which, as mentioned above, are  
26  
27 actually agglomerates of smaller particles (~ 1 μm). The consequence is that the Ti-Al sintering  
28  
29 additive is better distributed over the microstructure of the B<sub>4</sub>C compact, which is expected to  
30  
31 facilitate the subsequent densification and to result in more uniform B<sub>4</sub>C composites. These  
32  
33 observations on the as-cast pieces were nonetheless validated on the freeze-dried powder  
34  
35 mixtures. Certainly, the extensive SEM observations and EDS mappings, such as those shown by  
36  
37 way of example in Fig. 9, also evinced the much smaller size of the Ti-Al particles in relation to  
38  
39 their as-received condition.  
40  
41  
42  
43  
44

45         To conclude, we shall also present some preliminary SPS results as a complement to the  
46  
47 study of aqueous colloidal processing. In this regards, Fig. 10 shows SEM images of the fracture  
48  
49 surface of the two B<sub>4</sub>C composites, one fabricated from the freeze-dried powder mixture by SPS  
50  
51 at 1900°C for 30 min under 75 MPa pressure, and the other from the slip-cast (green) pieces by  
52  
53 pressureless SPS at 1900°C for 60 min. It can be seen that the former is fully dense (~2.676  
54  
55 g/cm<sup>3</sup> absolute density) and fine-grained, and that the latter is almost-fully dense (i.e., >95%) and  
56  
57  
58  
59  
60  
61  
62  
63  
64  
65

1  
2  
3  
4 coarse-grained due to its longer SPS cycle. Apparently, it may seem that the SPS temperature of  
5  
6 1900°C used here is too high when compared with earlier work on pure B<sub>4</sub>C [43], especially  
7  
8 because the use of Ti-Al additives should smooth the sintering conditions. Apart from the fact  
9  
10 that the SPS cycles are not optimized, it should be noted that different starting powders, and even  
11  
12 the same powders processed under different methods (for example used as-received, purified,  
13  
14 dispersed in water or in different alcohols, subjected to milling, etc.), may require different  
15  
16 sintering conditions. It is also important to mention that care must be taken when comparing the  
17  
18 SPS temperature reported here and in other studies because the present SPS furnace is equipped  
19  
20 with an axial optical pyrometer (focused on a deep hole machined across the upper graphite  
21  
22 punch), not with a radial optical pyrometer (focused close to the surface of the graphite die) as it  
23  
24 is more usual. Also note that the advantage of using these Ti-Al additives is undisputable  
25  
26 because a recent comparative study has demonstrated that they promote the complete  
27  
28 densification of B<sub>4</sub>C by transient liquid-phase sintering at SPS conditions (i.e., 1800°C (as  
29  
30 measured using a radial optical pyrometer) for 5 min under 32 MPa pressure) at which pure B<sub>4</sub>C  
31  
32 does not densify (i.e., ~15.5% porosity) [23]. Beyond the SEM observations of the fracture  
33  
34 surfaces carried out here (as needed in the context of the present study to discriminate on the  
35  
36 presence or absence of residual porosity), the fact is that this type of B<sub>4</sub>C composites has already  
37  
38 been characterized microstructurally in detail elsewhere [23] by XRD, SEM, transmission  
39  
40 electron microscopy, high-resolution electron microscopy, selected area electron diffractometry,  
41  
42 and electron probe microanalysis demonstrating that they possess a triple-particulate  
43  
44 microstructure formed by B<sub>4</sub>C grains (major phase) plus TiB<sub>2</sub> and Al<sub>3</sub>C<sub>4</sub> nanoparticles (very  
45  
46 minor phases formed in-situ during SPS from the reaction of the molten Ti-Al intermetallics with  
47  
48 B<sub>4</sub>C) located at both grain boundaries and multigrain joints, with no residual Ti-Al  
49  
50  
51  
52  
53  
54  
55  
56  
57  
58  
59  
60  
61  
62  
63  
64  
65

1  
2  
3  
4 intermetallics. By way of example, Fig. 11 shows the XRD pattern of the B<sub>4</sub>C composite SPS-ed  
5  
6 with pressure demonstrating the presence of TiB<sub>2</sub> and Al<sub>3</sub>C<sub>4</sub> also in the composites fabricated  
7  
8 here. Interestingly, the two B<sub>4</sub>C composites are superhard, although, due to its greater  
9  
10 densification, the one fabricated from the powder mixture by SPS with pressure is slightly harder  
11  
12 (i.e., 34±1 GPa) than the one fabricated from the slip-cast (green) pieces by SPS without pressure  
13  
14 (i.e., 32±1 GPa). These hardness values are consistent with the expected value (~33±1 GPa) for  
15  
16 fully dense and almost-fully dense B<sub>4</sub>C composites prepared with 5 vol.% Ti-Al (i.e., with ~7.33  
17  
18 wt.% Ti-Al) [23]. Finally, it should be mentioned that, although the SPS cycles with and without  
19  
20 pressure have yet to be conveniently optimized, these preliminary SPS tests at least demonstrate  
21  
22 the usefulness of the present route of aqueous colloidal processing for the future eco-friendly  
23  
24 fabrication of advanced B<sub>4</sub>C composites (once the SPS cycles have been appropriately adjusted  
25  
26 in subsequent studies).  
27  
28  
29  
30  
31  
32  
33  
34

#### 35 **4. Concluding Remarks**

36  
37 We have described a procedure of aqueous colloidal processing for the environmentally  
38  
39 friendly preparation of well dispersed concentrated suspensions, and therefrom powder mixtures,  
40  
41 of commercially available powders of submicrometre B<sub>4</sub>C (~0.6 μm) with coarse Ti-Al (~40  
42  
43 μm) as transient liquid-phase sintering additive. It was shown that B<sub>4</sub>C has little colloidal  
44  
45 stability in water, requiring very basic pH (i.e., pH>10) for its individual dispersion. Ti-Al has  
46  
47 greater colloidal stability than B<sub>4</sub>C, requiring quasi-neutral pH or above (i.e., pH>7.5) for its  
48  
49 individual dispersion. The addition of cationic (i.e., PEI) or anionic (i.e., PAA) deflocculants  
50  
51 simultaneously improves the colloidal stability of both B<sub>4</sub>C and Ti-Al, making their co-  
52  
53 dispersion possible at neutral pH (pH≤ 9 and pH≥5 when using PEI and PAA, respectively). It  
54  
55 was also shown that, although the concentrated suspensions (i.e., 30 vol.% total solids) can be  
56  
57  
58  
59  
60  
61  
62  
63  
64  
65

1  
2  
3  
4 deflocculated with PEI or PAA, the former are less viscous and thixotropic/rheopexic than the  
5  
6 latter and have the desirable shear-thinning rheological behaviour, being therefore preferable for  
7  
8 obtaining both powder mixtures by freeze-drying and green pieces by slip-casting. Finally,  
9  
10 preliminary SPS tests demonstrated the feasibility of fabricating superhard B<sub>4</sub>C composites from  
11  
12 these powder mixtures by conventional SPS with pressure or from the slip-cast (green) pieces by  
13  
14 pressureless SPS.

## Figure Captions

**Figure 1.** Dependence on pH and deflocculant content (PEI and PAA) of the zeta potential for the individual dilute suspensions of B<sub>4</sub>C and Ti-Al, as indicated. Dots are the experimental data, and the lines are guides for the eye. The grey stripe denotes the zone of low colloidal stability.

**Figure 2.** XPS spectra of the as-received B<sub>4</sub>C powder showing the (A) B 1s and (B) C 1s core-levels. Peak assignments are included.

**Figure 3.** XPS spectra of the as-received Ti-Al powder showing the (A) Ti 2p and (B) Al 2p core-levels. Peak assignments are included.

**Figure 4.** Optical photographs taken during the preparation of the B<sub>4</sub>C+5 vol.%Ti-Al concentrated suspensions with (A) 2 wt.% PAA, (B) 4 wt.% PAA, (C) 2 wt.% PEI, and (D) 4 wt.% PEI. Note that the slurries in (A) and (B) are very thick and resemble pastes, to such an extent that the helices used for the mechanical agitation left a residual imprint. The slurries in (C) and (D) are, however, very thin and resemble suspensions.

**Figure 5.** Flow curves of the B<sub>4</sub>C+5 vol.%Ti-Al concentrated suspensions prepared without sonication using as deflocculant 2 or 4 wt.% PEI or PAA. The arrows indicate, where applicable, the uploading and downloading stretches of the flow curves.

**Figure 6.** Flow curves of the B<sub>4</sub>C+5 vol.%Ti-Al concentrated suspensions prepared with (A) 2 or (B) 4 wt.% PEI as a function of sonication time. Sonication was not prolonged further once the flow curve worsened. The number at the right of each curve denotes the sonication time. The arrows indicate, where applicable, the uploading and downloading stretches of the flow curves.

- A route of aqueous colloidal processing of submicrometre B<sub>4</sub>C powder (~0.6 μm) with coarse Ti-Al powder (~40 μm) is presented and optimized.
- Concentrated suspensions of B<sub>4</sub>C+Ti-Al are prepared for the near-net shape manufacture of B<sub>4</sub>C composites by slip casting and pressureless spark plasma sintering.
- Powder mixtures of B<sub>4</sub>C+Ti-Al are prepared for the near-net shape manufacture of B<sub>4</sub>C composites by conventional spark plasma sintering.
- Superhard B<sub>4</sub>C composites are obtained in an environmentally friendly manner.
