### Abstract

The lubricated sliding-wear resistance of a fine-grained B<sub>4</sub>C composite fabricated by transient liquid-phase assisted spark-plasma sintering with Ti-Al additives at smooth conditions is critically compared to that of its reference monolithic B<sub>4</sub>C ceramic. It is shown that the former has an excellent sliding-wear resistance that exceeds that of the later by one order of magnitude (far less specific wear rate, worn volume, and wear damage), attributable to its greater hardness and densification. The wear mode is abrasion dominated by plastic deformation, plus localized microfracture in the monolithic ceramic. Implications for fabricating highly wear-resistant tribocomponents based on superhard ceramics are presented.

**Keywords:** B<sub>4</sub>C; superhard materials; wear; spark-plasma sintering; transient liquid-phase sintering.

2  
3  
4 B<sub>4</sub>C has been receiving great attention lately for the fabrication of superhard, ultra-  
5  
6 lightweight advanced ceramics for many structural applications, and especially for the  
7  
8 production of personnel/vehicle ballistic armours and a myriad of tribocomponents [1-10].  
9  
10 Unfortunately however, B<sub>4</sub>C is hardly at all densifiable in the pure state by conventional solid-  
11  
12 state sintering due to the kinetics limitations imposed by the strong covalent bonding and low  
13  
14 self-diffusion coefficients, as well as by the oxidic impurities (i.e., B<sub>2</sub>O<sub>3</sub> or H<sub>3</sub>BO<sub>3</sub>) favouring  
15  
16 coarsening over densification [4,11]. The undesirable consequence is that monolithic B<sub>4</sub>C  
17  
18 ceramics are generally porous to a greater or lesser extent, and are therefore softer and weaker  
19  
20 than expected –handicaps that in practice limit their potential in structural applications. It is then  
21  
22 understandable that conventional liquid-phase sintering has often been used palliatively to  
23  
24 consolidate B<sub>4</sub>C [4]. However, liquid-phase sintering is not entirely satisfactory either because  
25  
26 the residual intergranular phase irremediably degrades the hardness and refractoriness of the  
27  
28 resulting B<sub>4</sub>C composites [4].  
29  
30  
31  
32  
33  
34  
35

36 Interestingly, it has very recently been demonstrated that it is possible to fabricate at  
37  
38 moderate temperatures superhard, toughened, ultra-lightweight B<sub>4</sub>C composites with triplex-  
39  
40 particulate microstructures by spark-plasma sintering (SPS) using Ti-Al intermetallic additives  
41  
42 [12]. Ti-Al sintering aids have also been used to fabricate B<sub>4</sub>C composites by both hot-pressing  
43  
44 [13] and pressureless SPS [14]. This is because the Ti-Al intermetallic promotes the transient  
45  
46 liquid-phase sintering of B<sub>4</sub>C, first melting to help in the densification and then reacting with part  
47  
48 of B<sub>4</sub>C to form in-situ TiB<sub>2</sub> and Al<sub>3</sub>C<sub>4</sub> particles at grain boundaries and multigrain joints [12].  
49  
50 This is therefore an appealing and promising manner of circumventing the common drawbacks  
51  
52 of both the solid-state sintering and liquid-phase sintering of B<sub>4</sub>C, and merits complementary  
53  
54 research effort. The present work was aimed in this direction, and was undertaken with the main  
55  
56  
57  
58

60  
61  
62  
63  
64  
65

1  
2  
3  
4 objective in mind of evaluating for the very first time the sliding-wear resistance of these SPS-ed  
5  
6 B<sub>4</sub>C composites compared to that of the corresponding reference monolithic B<sub>4</sub>C ceramics  
7  
8 fabricated under the same SPS conditions. This type of comparative study is of primary  
9  
10 importance for those superhard/ultrahard ceramics that, as in the case of B<sub>4</sub>C, are or may become  
11  
12 very demanded for tribological applications requiring long-term durability, with the use of the  
13  
14 same SPS cycle being essential and therefore imposed here to elucidate the true potential of the  
15  
16 Ti-Al additives in making highly wear-resistant B<sub>4</sub>C tribocomponents at smoother sintering  
17  
18 conditions. In addition, evaluating the sliding wear of these advanced triboceramics is  
19  
20 particularly relevant because this contact condition is commonly encountered in myriad  
21  
22 applications, such as manufacturing-equipment components, dies, channels, bearings, seals,  
23  
24 valves, etc. Finally, as an added value, the present study also seeks to complement a previous  
25  
26 processing study with the so-far unreported analysis of the shrinkage rate curves logged during  
27  
28 SPS to further support the densification mechanism proposed for these B<sub>4</sub>C composites [12].  
29  
30  
31  
32  
33  
34

35  
36 The starting materials were commercially available submicrometre B<sub>4</sub>C ( $d_{50} \sim 0.5 \mu\text{m}$ ;  
37  
38 Grade HD 20, H.C. Starck, Germany) and micrometre Ti-Al ( $d_{50} \sim 40 \mu\text{m}$ ; TiAl, -325 mesh, Alfa  
39  
40 Aesar, Germany) powders. The B<sub>4</sub>C powder contains B<sub>4</sub>C plus impurities of C and H<sub>3</sub>BO<sub>3</sub>, while  
41  
42 the Ti-Al powder contains  $\gamma$ -TiAl (major phase),  $\alpha_2$ -Ti<sub>3</sub>Al (minor phase), and TiAl<sub>2</sub> (minor  
43  
44 phase). The two powders were then combined in a B<sub>4</sub>C:Ti-Al wt.% ratio of 95:5, and the powder  
45  
46 mixture was ball-milled in methanol for 24 h. Methanol was used as liquid medium to eliminate  
47  
48 the oxidic impurities in the B<sub>4</sub>C powder, as demonstrated elsewhere [15,16]. Moreover, this  
49  
50 specific composition with 5 wt.% Ti-Al additive was chosen on the basis of an earlier processing  
51  
52 study showing the optimization of the mechanical properties (hardness, toughness, and strength)  
53  
54 of the resulting B<sub>4</sub>C composites [12]. The slurry was subsequently dried under continuous  
55  
56  
57  
58

2  
3  
4 agitation, and the resulting dried powder mixture was finally deagglomerated. The B<sub>4</sub>C starting  
5  
6 powder was also methylated and dried under identical conditions to those of the B<sub>4</sub>C+5 wt.%Ti-  
7  
8 Al powder mixture, and used to fabricate a reference monolithic B<sub>4</sub>C ceramic. Next, the  
9  
10 methylated B<sub>4</sub>C powder and the B<sub>4</sub>C+5wt.%Ti-Al powder mixture were individually loaded into  
11  
12 graphite dies lined with graphite foils and surrounded by graphite blankets, and both were then  
13  
14 SPS-ed (HP D 10, FCT Systeme GmbH, Germany) in dynamic vacuum (i.e., ~3 Pa) at 1800 °C  
15  
16 (100 °C/min heating ramp) for 5 min under 50 MPa (applied at 300 °C). After completion of the  
17  
18 SPS cycle, the load was released and the electrical power was shut off to allow rapid cooling (in  
19  
20 1-2 min) to room temperature. The two resulting materials (discs of 2-cm diameter and 1-cm  
21  
22 thickness) were ground and diamond polished to a 1-μm finish, and then characterized  
23  
24 microstructurally by X-ray diffractometry (XRD; D8 Advance, Bruker AXS, Germany) and  
25  
26 scanning electron microscopy (SEM; Quanta 3D, FEI, The Netherlands).  
27  
28  
29  
30  
31  
32

33  
34 Fig. 1 shows representative SEM images (both polished and fracture surfaces) and the  
35  
36 XRD patterns, of both the reference monolithic ceramic and the composite fabricated in the  
37  
38 present study by SPS under the same conditions without and with Ti-Al additives, respectively.  
39  
40 There are evident microstructural differences between them. In particular, Figs. 1A, 1C, and 1E  
41  
42 show that the reference monolithic ceramic has a fine-grained (< 1 μm), porous (~10%; absolute  
43  
44 density of ~2.26 g/cm<sup>3</sup>) microstructure with only B<sub>4</sub>C plus some residual graphite (the only  
45  
46 impurity present in the B<sub>4</sub>C powder purified in methanol). This corroborates the poor solid-state  
47  
48 sinterability of pure B<sub>4</sub>C, even under SPS. The residual porosity of this reference monolithic  
49  
50 ceramic is responsible for its low hardness of only 18.9±0.6 GPa [12,17], as measured here  
51  
52 experimentally by Vickers indentation tests (MV-1, Matsuzawa Seiki Co., Japan) at both 9.8 and  
53  
54 49 N using standard procedure and formula [18,19]. As observed in Figs. 1B, 1D, and 1F, the  
55  
56  
57  
58  
59  
60  
61  
62  
63  
64  
65

1  
2  
3  
4 composite is however essentially dense (absolute density of  $\sim 2.59 \text{ g/cm}^3$ ), and has a more  
5  
6 complex fine-grained ( $\sim 0.7\text{-}0.8 \text{ }\mu\text{m}$ ) microstructure with secondary phases located at both grain  
7  
8 boundaries and multigrain joints (as demonstrated by transmission electron microscopy (TEM)  
9  
10 elsewhere [12]). It contains  $\text{B}_4\text{C}$  and some graphite, plus  $\text{TiB}_2$ ,  $\text{Al}_4\text{C}_3$ ,  $\text{TiO}_2$ , and  $\text{Al}_2\text{O}_3$  as other  
11  
12 minor phases, but not  $\gamma\text{-TiAl}$ ,  $\alpha_2\text{-Ti}_3\text{Al}$ , or  $\text{TiAl}_2$  used as sintering additives. It is therefore not a  
13  
14 cermet (i.e., ceramic grains embedded into a metallic matrix), but a multi-particulate ceramic  
15  
16 composite with a superhardness of  $32.9\pm 0.7 \text{ GPa}$  (as also measured by Vickers indentation tests).  
17  
18  
19  
20

21 The processing of  $\text{B}_4\text{C}$  composites by SPS with Ti-Al additives has been studied  
22  
23 elsewhere [12], demonstrating by a thorough microstructural characterization that densification  
24  
25 occurs by transient liquid-phase sintering [12]. This is consistent with the present study on other  
26  
27  $\text{B}_4\text{C}$  starting powder (with finer particle size) with nominally the same Ti-Al additive. Besides  
28  
29 these microstructural observations, the so-far unused analysis of the shrinkage rate curves logged  
30  
31 during SPS could also validate the correctness of this densification mechanism. Indeed, Fig. 2  
32  
33 shows that the  $\text{B}_4\text{C}+5\text{wt.}\%\text{Ti-Al}$  powder mixture exhibits a distinctive peak of accelerated  
34  
35 shrinkage rate at  $\sim 1400 \text{ }^\circ\text{C}$  (confirmed using a  $\text{B}_4\text{C}+7\text{wt.}\%\text{Ti-Al}$  powder mixture), attributable to  
36  
37 the formation of a liquid phase that spreads rapidly between particles, filling pores [20]. This is  
38  
39 the expectation derived from the Ti-Al binary phase diagram [21], in particular because the  
40  
41 temperature within the SPS die is higher than that measured by the optical pyrometer.  
42  
43 Nonetheless, despite the formation of a liquid phase there is little grain growth by solution-  
44  
45 reprecipitation because the Ti-Al intermetallic acts as a reactive and transient liquid-phase  
46  
47 sintering additive, not as a permanent liquid-phase sintering additive.  
48  
49  
50  
51  
52  
53  
54  
55

56 Fig. 3A shows the sliding-wear curves (i.e., wear volume ( $V$ ) vs sliding distance ( $L$ )) of  
57  
58 both the reference monolithic ceramic and the composite fabricated by SPS and then diamond  
59  
60  
61  
62  
63  
64  
65

1  
2  
3  
4 polished to a 1- $\mu\text{m}$  finish. The tribological tests (Falex multi-specimen, Faville-LeVally Corp.,  
5 USA) were carried out in the ball-on-three-disks geometry under total lubrication conditions (to  
6 thus avoid friction-induced heating or triboreactions), using a commercial bearing-grade  $\text{Si}_3\text{N}_4$   
7 ball (NBD200, Cerbec, USA) of radius 6.35 mm as counterpart, paraffin oil as lubricant (with  
8 viscosity of 34 cSt at 40 °C), a total normal contact load of 212 N (to thus apply 50 N of normal  
9 load on each disk (flat specimen of  $\sim 3.5 \times 3.5 \times 2.0 \text{ mm}^3$ )), and a rotation speed of 100 rpm  
10 (corresponding to a sliding velocity of  $\sim 0.047 \text{ m/s}$ ). The wear tests were selectively interrupted  
11 to evaluate the size of the wear scar on the reference monolithic ceramic and the composite as a  
12 function of the sliding time by optical microscopy (OM; Epiphot 300, Nikon, Japan), from which  
13 worn volumes were computed as a function of the sliding distance [22] and used to calculate the  
14 specific wear rates. It can be seen in Fig. 3A that both materials show a characteristic two-stage  
15 curve, observed in other polycrystalline ceramics [10,23-25]. In particular, an initial run-in stage,  
16 in which the wear volume quickly increases until the test specimens accommodate the rotating  
17 countersphere at a sliding distance of  $\sim 150 \text{ m}$ , is followed by a steady-state stage. In this second  
18 stage, the wear volume increases linearly with the sliding distance. It is clear that the wear  
19 resistance of the composite is dramatically improved with respect to that of the reference  
20 monolithic ceramic. Indeed, for each value of the sliding distance, the wear volume of the  
21 composite is one order of magnitude lower than that of the reference monolithic ceramic. The  
22 wear rate calculated using the data in the steady-state stage is also significantly lower in the  
23 composite than in the reference monolithic ceramic:  $(1.9 \pm 0.2) \cdot 10^{-16}$  vs  $(1.99 \pm 0.09) \cdot 10^{-15} \text{ m}^3/\text{m}$ .  
24 The corresponding specific wear rates are  $(3.8 \pm 0.4) \cdot 10^{-18}$  (composite) and  $(4.0 \pm 0.2) \cdot 10^{-17} \text{ m}^3/\text{Nm}$   
25 (reference monolithic), which are characteristic of materials with excellent and good wear  
26 resistance, respectively [26]. The wear and specific wear rates measured for the reference  
27

1  
2  
3  
4 monolithic ceramic are consistent with those reported earlier (i.e.,  $(1.72\pm 0.17)\cdot 10^{-15} \text{ m}^3/\text{m}$  and  
5  
6  $(2.9\pm 0.29)\cdot 10^{-17} \text{ m}^3/\text{Nm}$ ) for a near-fully dense ( $\sim 95\%$ ) monolithic  $\text{B}_4\text{C}$  ceramic [10]. Thus, the  
7  
8 composite exhibits a sliding-wear resistance that exceeds that of the reference monolithic  
9  
10 ceramic by one order of magnitude (i.e.,  $(2.6\pm 0.3)\cdot 10^{17}$  vs  $(2.5\pm 0.5)\cdot 10^{16} \text{ Nm/m}^3$ ).  
11  
12  
13

14 The patent differences between the wear resistance of the materials observed in Fig. 3A  
15  
16 can be clearly visualized in Fig. 3B, which compares optical micrographs of the wear scars at the  
17  
18 conclusion of the tests. Indeed, the scar in the composite is remarkably smaller than that in the  
19  
20 reference monolithic ceramic. Moreover, clear differences in the damage mechanisms can be  
21  
22 observed at this level of magnification. In particular, the composite shows only seemingly  
23  
24 superficial scratches running parallel to the sliding direction. The reference monolithic ceramic  
25  
26 shows deeper grooves, accompanied by relatively large, dark patches (pits) indicative of in-depth  
27  
28 material removal by grain pullout.  
29  
30  
31  
32

33 Fig. 4 show higher magnification details of the damage inside the wear scars. As  
34  
35 anticipated, the damage at the microstructural scale is more severe in the case of the reference  
36  
37 monolithic ceramic, which exhibits a larger amount of wider and deeper grooves compared to the  
38  
39 composite. In particular, Fig. 4A shows grooves of width up to  $\sim 20 \mu\text{m}$  in the reference  
40  
41 monolithic ceramic, along with the material porosity. The grooves appear to be relatively deep,  
42  
43 resulting in a rough wear surface, and contain abundant debris, as observed in Fig. 4B. Inside the  
44  
45 pitted regions, material removal (i.e., grain pullout) takes place from even deeper under the  
46  
47 surface, and crushed particles and microcracks can be observed (Figs. 4C and D). In contrast, the  
48  
49 worn surface of the composite appears to be quite smooth and polished, and mostly contains very  
50  
51 superficial scratches of width  $\sim 1\text{-}5 \mu\text{m}$  (Figs. 4E-G).  
52  
53  
54  
55  
56

57 The wear markings observed by OM and SEM suggest that both the reference monolithic  
58  
59  
60  
61  
62  
63  
64  
65

1  
2  
3  
4 ceramic and the composite wear by abrasion, caused by either the asperities of the countersphere  
5  
6 (two-body wear), and/or by dislodged particles trapped under the contact (three-body wear)  
7  
8  
9 [26,27]. The dominant wear mechanism is plastic deformation at the asperity/particle level,  
10  
11 responsible for the grooves and scratches. Since the resistance to plastic deformation ultimately  
12  
13 depends on the material hardness, the wear volume is expected to correlate inversely with  
14  
15 hardness ( $V \propto H^{-1}$ ) according to the classical Archard's wear law [28,29]. Thus, the superior wear  
16  
17 resistance of the composite is largely a result of its almost twofold greater hardness compared to  
18  
19 the reference monolithic ceramic (~33 vs 19 GPa). Another two factors which contribute to the  
20  
21 higher wear resistance of the composite are its great densification and small amount of wear  
22  
23 debris generated by grain pullout. This is because the porosity provides critical defects from  
24  
25 which fracture can initiate, as evidenced by the larger extent of microcracking observed inside  
26  
27 the pitted regions in the reference monolith ceramic (Figs. 4C and D), resulting in more in-depth  
28  
29 material removal by grain pullout. The hard wear debris generated, in turn, contributes to a  
30  
31 greater extent of third-body abrasion. Last, it is worth noting that the lubrication conditions are  
32  
33 not expected to affect the wear mechanism, only the severity of the wear damage and rate.

34  
35  
36  
37  
38  
39  
40  
41 An interesting final consideration is that earlier tribological studies have shown the  
42  
43 relevance of subtle differences of densification in the wear resistance of superhard/ultrahard  
44  
45 carbides [23,24]. In particular, it has been observed that near-fully dense monolithic ZrC  
46  
47 ceramics have lower sliding-wear resistance than ZrC composites fully densified with MoSi<sub>2</sub>  
48  
49 (which also acts as a transient liquid-phase sintering additive), which is indeed the same  
50  
51 conclusion reached here for the case of B<sub>4</sub>C triboceramics. Fabrication of these advanced  
52  
53 triboceramics under SPS at smoother conditions (i.e., at lower temperature to minimize grain  
54  
55 growth) without compromising their full densification (for example using transient liquid-phase  
56  
57  
58  
59  
60  
61  
62  
63  
64  
65

1  
2  
3  
4 sintering additives) thus emerges as a likely generic processing guideline to make them highly  
5  
6 sliding-wear resistant.  
7

(1965).

## Figure Captions

**Figure 1.** SEM micrographs of the electrochemically-etched (using 1% KOH solution at a current density of  $0.05 \text{ A/cm}^2$  for 30 s), diamond-polished surface (to a 1- $\mu\text{m}$  finish) of (A) the reference monolithic  $\text{B}_4\text{C}$  ceramic and (B) the  $\text{B}_4\text{C}$  composite, as well as of the fracture surface of (C) the reference monolithic  $\text{B}_4\text{C}$  ceramic and (D) the  $\text{B}_4\text{C}$  composite. The insets in (A) and (B) are lower magnification micrographs. The sinkholes in (B) are not pores, but regions of second phases removed by the etching process [12]. XRD patterns of the (E) reference monolithic  $\text{B}_4\text{C}$  ceramic and (F) the  $\text{B}_4\text{C}$  composite. Peak assignments are included.

**Figure 2.** Shrinkage rate curve logged during the SPS cycle as a function of temperature for the  $\text{B}_4\text{C}$  powder and for the powder mixtures of  $\text{B}_4\text{C}$  with 5 and 7 wt.% Ti-Al. This last was measured to merely confirm the existence of a peak of accelerated shrinkage rate in the powder mixtures of  $\text{B}_4\text{C}$  with Ti-Al.

**Figure 3.** (A) Wear curves for the reference monolithic  $\text{B}_4\text{C}$  ceramic and the  $\text{B}_4\text{C}$  composite. Dots are the experimental data, whereas the solid lines are included as guides to the eye. The inset shows a detailed view of the wear curve of the  $\text{B}_4\text{C}$  composite up to a sliding distance of 150 m. (B) Composition of optical images of the residual wear scars in the reference monolithic  $\text{B}_4\text{C}$  ceramic and in the  $\text{B}_4\text{C}$  composite at the end of the wear tests. The same scale bar is used intentionally to ensure the straightforward visual comparison of the wear-scar sizes.

**Figure 4.** SEM micrographs of the damage within the wear scar of the reference monolithic  $\text{B}_4\text{C}$  ceramic taken within the grooves at (A) moderate and (B) high magnifications, and within the pitted regions at (C) low and (D) moderate magnifications, as well as SEM micrographs of the damage within the wear scar of the  $\text{B}_4\text{C}$  composite taken at (E) low, (F) moderate, and (G) high
