23 **Abstract**

24 Laboratory and field experiments were conducted on three Mediterranean agricultural soils in so as to investigate the
25 effects of de-oiled two-phase olive mill waste (D) and two-phase olive mill waste (W) and their level of organic matter
26 maturity on the environmental fate of the herbicide S-metolachlor (SM). Three Mediterranean agricultural soils were
27 amended with fresh (D and W) and composted W (CW) wastes under laboratory conditions. Furthermore, under field
28 conditions, one of the soils was also amended with both wastes (D and W) over 9 years in order to assess the effects of
29 the “aging” transformation (AD and AW treatments, respectively). Significant increases in SM adsorption were
30 observed in all the amended soils, with no reduction in the herbicide's effectiveness. The adsorption process was more
31 reversible with the fresh organic amendments (D or W) than with CW or (even more so) with AD or AW. The fresh
32 amendments also increased the persistence of SM; however the field-aged and composted amendments enhanced its
33 dissipation as a result increased soil microbial activity showed by high levels of soil dehydrogenase activity. The AD-
34 and AW-amended soils, showed the greatest decrease in leaching loss of SM (from 51.9% in original soil to 9.33% in
35 AD and 8.05% in AW), reflecting the strong influence of adsorption-desorption processes on SM leaching. This study
36 has shown that the application of olive mill wastes as organic amendments may be considered a useful strategy to
37 reduce leaching of SM in soils poor in organic matter, especially if those wastes have a high level of organic matter
38 maturity.

39

40 **Keywords** – Adsorption; Dehydrogenase activity; Dissipation; Leaching; Olive mill waste; S-metolachlor

41

42 **Abbreviations:** SM, S-metolachlor; W, two-phase olive mill waste; D, de-oiled two-phase olive mill waste; HPLC,
43 high-performance liquid chromatography; CW, composted two-phase olive mill waste; AD, aged de-oiled two-phase
44 olive mill waste; AW, aged two-phase olive mill waste; TOC, total organic carbon; HA, humic acids; FA, fulvic acids;
45 WSOC, water-soluble organic carbon; HI, humification index; EC, electrical conductivity; DHA, Dehydrogenase
46 activity; H, hysteresis coefficients

47 **Effects of olive mill wastes with different degrees of maturity on behaviour of S-metolachlor in three soils**

48 **1. Introduction**

49 The herbicide S-metolachlor (SM) is widely used to control weeds in different crops such as maize, soybean, cotton,
50 and tomato as a selective chloroacetanilide herbicide. Indeed, SM is one of the ten most used active ingredients in the
51 European Union (Eurostat and European Commission, 2007). In the environment, SM has been detected in samples of
52 waters at superior concentrations to $0.1 \mu\text{g L}^{-1}$, limit established by the European Union for drinking water (Palma et
53 al., 2014; Pérez et al., 2010). This is due to its high water solubility (488 mg L^{-1}), intensive use, low retention potential,
54 and high persistence in soils (Peña et al., 2013; López-Piñeiro et al., 2014). It is therefore quite important to develop
55 effective strategies to avoid or reduce water contamination by SM.

56 Mediterranean agricultural systems are environments at high risk of water pollution by herbicides, mainly because their
57 soils are very often poor in organic matter content (Gámiz et al., 2012). Hence, the application of organic amendments
58 to agricultural soils is a common agronomic practice to increase crops productivity and soils fertility. However, this
59 practice strongly influences the properties of the soil, and can thus affect the adsorption-desorption, dissipation, and
60 leaching of pesticides (e.g., García-Jaramillo et al., 2016; Kerminen et al., 2018; Trigo et al., 2016).

61 In Spain, the current process used in olive oil extraction generates a main by-product which is known as two-phase
62 olive mill waste (W). Generally, W is subjected to extraction to recover the oil still present, process that generates a by-
63 product, which is known as de-oiled two-phase olive mill waste (D). In the Mediterranean region, more than 15 Mt of
64 these wastes are produced during the months of October-December each year (Volpe et al., 2018), which constitutes a
65 critical issue for the industry. These wastes (W and D) are characterised by a high organic matter contents and plant
66 mineral nutrients, as well as lack pathogenic organisms and heavy metals. Therefore, its application to soils as organic
67 amendments, whether fresh or composted, may be a great alternative for their disposal (Gámiz et al., 2012; Peña et al.,
68 2016; Serramiá et al., 2013). Moreover, such waste management practices would be found according to the Circular
69 Economy Strategy of the European Union (COM, 2017), based on resources are conserved and waste is reused. It is
70 especially important to assure the suitable management of organic waste (Hueso-González et al., 2018).

71 Different studies have observed that the application of W and D represents an inexpensive source of nutrients for the
72 crops that could replace the need for chemical fertilizers (Ayoub et al., 2014; Vella et al., 2016), and can enhance crop
73 yields (Chatzistathis & Koutsos, 2017). In addition, the application of W and D as organic amendments can modify the
74 properties of the soils, and therefore also the environmental behaviour of herbicides (Delgado-Moreno et al., 2017;
75 López-Cabeza et al., 2017; López-Piñeiro et al., 2014). Generally, the adsorption of herbicides increases with increasing
76 of organic matter content in the soil, and thus their mobility decreases. However, the fate of herbicides in amended soils
77 is a difficult subject because the effects depends on many factors, such as the soil and amendment types, the organic

78 matter content and its degree of maturity, amendment dosage, pH, microbial activity (García-Delgado et al., 2019;
79 Wolejko et al., 2017). In addition, the interactions between pesticides and soils may be affected by the evolution and
80 transformation of the amendment's organic matter under field conditions (Morillo et al., 2002). On the other hand, the
81 properties of the herbicides as their molecular configuration and size, dissociation constant, and water solubility are
82 important factors that affect their behaviour (Mendes et al., 2016). In this sense, the determination of the impacts of W
83 and D on the behaviour of SM in different type of soils would provide valuable information about the safe and effective
84 use of the herbicide in agro-ecosystems.

85 Although several studies have clearly shown that the application of W and D to soils may provide beneficial effects in
86 soil properties and crop productivity, we only found three studies (Cañero et al., 2015; López-Piñeiro et al., 2014; and
87 Peña et al., 2013) analysing the effects of olive mill wastes on SM behaviour. These studies, however, considered only
88 amendments with the same degree of organic matter maturity and/or only one type of soil.

89 Previous studies have demonstrated the great importance of the nature and/or degree of decomposition of the organic
90 matter on pesticide adsorption (Aslam et al., 2013; Cassigneul et al., 2015). In the particular case of olive mill wastes,
91 López-Piñeiro et al. (2013a) reported that the highest sorptive capacity for metribuzin was observed with composted
92 olive waste, suggesting that the total organic carbon (TOC) content may not be the principal factor in metribuzin
93 adsorption. Similar results were found by Haberhauer et al. (2001) who observed that in case of MCPA herbicide, an
94 increase of TOC does not necessarily imply an increase on adsorption capacity. However, Cabrera et al. (2010) and
95 López-Piñeiro et al. (2012) found lower K_f coefficients with aged than with fresh amendments to diuron and
96 terbuthylazine herbicides, respectively, due to the lower TOC content observed with aged amendments. These results
97 seems to indicate that the maturity of the organic matter has be to taken into account, since not all organic matter has the
98 same effectiveness for the herbicides sorption (Morillo et al., 2002). Therefore, the objective of the present study was to
99 investigate the effects of olive mill wastes application at different degrees of maturity (fresh, composted, and field-
100 aged) on SM adsorption-desorption, dissipation, and leaching in three Mediterranean agricultural soils. The influence of
101 the olive mill wastes application as organic amendments on the microbial activity of the soil was also analysed due to
102 herbicide persistence largely depends on microbial degradation.

103 **2. Material and Methods**

104 **2.1. Herbicide and assays**

105 SM of 96.0 ± 1.0 % purity was purchased from Dr Ehrenstorfer GmbH and its properties were 283.8 g mol^{-1} molecular
106 weight, 3.7 mPa vapour pressure at 25°C , and 480 mg L^{-1} water solubility at 25°C (BPDB, 2019). For assays, the SM
107 solutions were prepared with this product. High-performance liquid chromatography (HPLC) was used to quantify the
108 herbicide in the different tests. The limits of detection and quantification, calculated as the herbicide concentrations

109 resulting in signal-to-noise ratios of 3:1 and 10:1, respectively, were 0.061 μM and 0.204 μM , respectively. The
110 conditions of the HPLC analysis are described in text S1 of the Supplementary Material.

111 **2.2. Organic amendments and soils**

112 Two organic amendments (D and W), each with different degree of maturity (fresh, composted, and field-aged), were
113 used in this study. The fresh D and W were obtained from olive oil industries in Beja and Portalegre (Portugal),
114 respectively. The composting process of W (CW) was carried out over 10 months (8 months on a pilot scale and 2
115 months more for maturation) in a trapezoidal pile with occasional turning and olive leaves added as bulking agent, with
116 water added regularly to maintain appropriate moisture. The physicochemical characteristics of these wastes are given
117 in Table 1.

118 Three Mediterranean agricultural soils were used in the present study: a loam soil (S1) that contained 239 g kg^{-1} clay,
119 324 g kg^{-1} silt, and 437 g kg^{-1} sand, a sandy loam soil (S2) that contained 142 g kg^{-1} clay, 323 g kg^{-1} silt, and 535 g kg^{-1}
120 sand. Both soils (S1 and S2) were located in intensive farming systems in the plains of the Guadiana river near to city of
121 Badajoz (Spain), (38°54'N –6°54'W) for S1 and (38°54'N –6°53'W) for S2. The other soil, a sandy clay loam soil (S3)
122 that contained 297 g kg^{-1} clay, 211 g kg^{-1} silt, and 492 g kg^{-1} sand was located on a representative olive grove in Elvas,
123 Portugal (38°53'N–6°59'W). The soil samples (0-30 cm depth) were dried at room temperature and sieved through a 2
124 mm mesh screen.

125 In the laboratory, two doses (2.5% and 5% by dry weight) of fresh wastes (D and W) and composted W (CW) were
126 applied separately for each to original soils in order to investigate the impacts of these organic amendments on SM
127 behaviour. Hence the resulting amended samples are labeled as S1D2.5 and S1D5, S2D2.5 and S2D5, and S3D2.5 and
128 S3D5 (2.5% and 5% of D for each of the S1, S2, and S3 soils, respectively), S1W2.5 and S1W5, S2W2.5 and S2W5,
129 and S3W2.5 and S3W5 (2.5% and 5% of W for each of the S1, S2, and S3 soils, respectively), and S1CW2.5 and
130 S1CW5, S2CW2.5 and S2CW5, and S3CW2.5 and S3CW5 (2.5% and 5% of CW for each of the S1, S2, and S3 soils,
131 respectively). Additional information on how the mixtures were made can be found in text S2 of the Supplementary
132 Material.

133 Field experiment in olive grove of the soil S3 was conducted to investigate the effects of the "aging" transformation of
134 the D and W organic matter on SM behaviour. For this purpose, besides the original S3 soils, four treatments were
135 selected which consisted 27 $\text{Mg D ha}^{-1} \text{ yr}^{-1}$ (equivalent to 0.56% yr^{-1} , S3AD5) and 54 $\text{Mg D ha}^{-1} \text{ yr}^{-1}$ (equivalent to
136 1.12% yr^{-1} , S3AD10), 30 $\text{Mg W ha}^{-1} \text{ yr}^{-1}$ (equivalent to 0.62% yr^{-1} , S3AW5), and 60 $\text{Mg W ha}^{-1} \text{ yr}^{-1}$ (equivalent to
137 1.24% yr^{-1} ; S3AW10), dry weight equivalents. In this experiment, both amendments have been applied for 9
138 consecutive years. Additional information on how the mixtures were made can be found in text S2 of the
139 Supplementary Material. Thus, the total amounts of olive mill wastes applied to the field-amended soil and laboratory-

140 amended soils were similar. For this reason, in the laboratory, the S3 soil was also amended with 10% of fresh D and
141 W, labeled as S3D10 and S3W10, respectively. Selected properties of the original and amended soils are shown in
142 Table 2.

143 **2.3. Analysis of the organic amendments and soils**

144 The properties of the soils and wastes (D, W and CW) analysed were: total organic carbon (TOC), water-soluble
145 organic carbon (WSOC), electrical conductivity (EC) and pH. Humic acids (HA) and fulvic acids (FA) were extracted
146 with 0.1 M of tetrasodium pyrophosphate, and to precipitate HA the supernatant was acidified to pH 2 with sulphuric
147 acid. The TOC associated with each fraction of HA and FA was determined by dichromate oxidation and measurement
148 of the absorbance at 590 nm. The Humification index (HI) was calculated as $((\text{HA}/\text{TOC}) \times 100)$.

149 These analyses were developed as described by Peña et al. (2016).

150 **2.4. Adsorption-desorption studies**

151 Adsorption-desorption studies were developed as described by López-Piñeiro et al. (2014). Briefly, the SM
152 concentrations used were 5, 10, 20, 40, and 50 μM . Following the adsorption analysis, desorption of the SM was
153 studied, replacing the 5 mL of the supernatant removed for the adsorption analysis with 5 mL of 0.01 M CaCl_2 .
154 Although Freundlich, Langmuir, and linear models were tested, the sorption kinetics of SM were best described by the
155 Freundlich model which produced the best fit with the highest regression coefficients and lowest sum of squared errors.
156 A complete description of the methodology can be found in text S3 of the Supplementary Material.

157 **2.5. Dissipation of SM**

158 The dissipation study was carried out according to the conditions described in Peña et al. (2013). Briefly, the herbicide
159 was applied to get 1.5 mg SM kg^{-1} of concentration. Herbicide-treated soil samples were incubated for 103 days at
160 $20 \pm 2^\circ\text{C}$. Periodically, soils samples were taken and then frozen until assay. Although biphasic and first-order
161 multicompartament models were also tested, dissipation of SM was best described by a first-order kinetics model. This
162 produced the best fit with the highest regression coefficients and lowest sum of squared errors. For this reason, first-
163 order kinetics was used to analyse the dissipation data of this herbicide and to calculate the half-life ($t_{1/2}$) (this last was
164 done after fitting the data to a first-order kinetics equation). A complete description of the methodology can be found in
165 text S4 of the Supplementary Material.

166 **2.6. Dehydrogenase activity**

167 Dehydrogenase activity (DHA) was determined following the method described in García et al. (1993). A complete
168 description of the methodology can be found in text S5 of the Supplementary Material.

169 **2.7. Column leaching tests**

170 Disturbed soil columns were used to the leaching experiments as described by Peña et al. (2016). A concentration of 1.5
171 mg of SM kg⁻¹ was added to the top of the columns and, then 50 mL of calcium chloride was applied to leach the
172 columns every day. At the end of the leaching tests, the columns were sectioned into 5-cm deep portions in order to
173 determine the residual amount of SM at the different depths of the soil column. A complete description of the leaching
174 study is shown in text S6 of the Supplementary Material.

175 **2.8. Herbicide extraction**

176 For soils samples of the dissipation and leaching studies, SM were extracted with methanol using a ratio of 2:1 (v/w) by
177 shaking mechanically for 24 hours in an end-over-end shaker at 20±2°C. Then, the samples were centrifuged the
178 samples for 7 minutes at 3500 rpm and filtered. Finally, the SM concentration in the extracts was determined by HPLC.
179 Preliminary studies showed that this extraction procedure recovered ≥95% of the SM applied to the soils.

180 **2.9. Bioassays**

181 In order to assess how application of the organic amendments affected SM's efficacy, its antigermination potential was
182 measured on *Lolium perenne* L., due to is a plant sensitive to SM. The treatments selected for this experiment were: S1,
183 S1D5, S1W5, S1CW5, S2, S2D5, S2W5, S2CW5, S3, S3D5, S3D10, S3W5, S3W10, S3CW5, S3AD10, and S3AW10.
184 In each case, two sets of pots were carried out, one set with SM applied at a dose rate of 1.5 kg ha⁻¹, and the other set
185 without herbicide to be used as controls. 50 seeds were carefully spread by hand on the surface of the soil in the pot as
186 homogeneously as possible before the SM application. The pots were under optimal conditions for germination. After
187 14 days of the sowing, the seedlings in each pot were counted and their lengths measured.

188 **2.10. Statistical analysis**

189 IBM SPSS Statistics 22.0 program was used to the statistical test. The results were subjected to a one-way ANOVA
190 model and multiple pairwise comparisons were performed using the Duncan test to determine significant differences
191 between results at a $p < 0.05$ level of probability. Pearson's correlation coefficient was employed to find possible
192 correlations between the various parameters.

193 **3. Results and Discussion**

194 **3.1. Adsorption-desorption studies**

195 The experimental data of the adsorption-desorption studies fit Freundlich equation well, with $R^2 \geq 0.944$ (Table 3). A
196 high level of linearity was observed for the SM adsorption isotherms ($n_f \approx 1$, Table 3), especially with the fresh and
197 aged amendments (D, W, AD, and AW). This behaviour is coherent with that observed by Peña et al. (2013) for SM

198 adsorption in a Cutanic Luvisol using D- and W-amendments. However, Baran & Gourcy (2013) found n_f values of less
199 than unity for SM in different agricultural soils, showing that the soil's affinity for the herbicide molecules decreases as
200 the herbicide concentration increases. The k_f values for SM adsorption in the original soils ranged from 1.41 for S3 to
201 3.02 for S1. These relatively low values agree with Cañero et al. (2015) who found values of 1.0 and 1.57 in a sandy
202 soil and a clayey soil, respectively, and suggest that these soils have a very weak capacity to bind SM. The low TOC
203 content observed in the soils of the present study could be the reason to the relatively low k_f values found. Indeed, for
204 some soils in the USA with TOC values from 8.70 to 32.5 g kg⁻¹, much higher than those of our study (Table 2), Shaner
205 et al. (2006) reported k_f values ranging from 1.58 to 6.93. Likewise, Bedmar et al. (2011) report a k_f of 29.2 in a no-
206 tillage soil for four years, with a TOC value of 25 g kg⁻¹. The fresh amendments (D and W) had a significant influence
207 on the adsorption of SM (Table 3). Their k_f values were greater than those of the original soils; however the magnitudes
208 are different between soil and according to the amendment applied. Thus, for the 5% D applications, the k_f was greater
209 by factors of 1.33 in S1, 2.11 in S2, and 3.60 in S3, whereas for the 5% W applications, the corresponding factors were
210 2.00 in S1, 3.01 in S2, and 4.82 in S3. These results suggest that W had a higher affinity for SM than D. Similar
211 findings had been found by Albarrán et al. (2003) for simazine sorption, with the increase produced by a D amendment
212 being significantly less pronounced than that found with a W amendment. These differences may be due to not only to
213 the higher TOC content of W (535 g kg⁻¹) than of D (516 g kg⁻¹), but especially to the higher HA content of W (51.8 g
214 kg⁻¹) than of D (30.7 g kg⁻¹). In fact, in our study, k_f was positively and significantly ($p<0.01$) correlated with HA
215 ($r=0.744$), and this correlation was higher than that with TOC ($r=0.657$).

216 The adsorption of SM was greater in the soils amended with W than CW (Table 3). This could be attributable to the
217 higher content of TOC into the fresh W-amended soils than the CW-amended soils (Table 2). In particular, for 5% of
218 fresh W treatments, the TOC content increased by factors of 3.54, 4.85, and 4.11 in S1, S2, and S3, respectively,
219 whereas, for 5% of composted W (CW treatments), the factors were 2.73, 3.83, and 2.67 in S1, S2, and S3, respectively.

220 Previous work with SM has found that SM sorption coefficients were correlated with the soil's organic matter content
221 (Patakioutas & Albanis, 2002; Westra et al., 2015).

222 In the field-amended soils, the application of both amendments (D and W) significantly ($p<0.05$) increased SM
223 adsorption (Table 3). The increase was greater in the D-amended soils, suggesting that D had a higher affinity for SM
224 than W when both wastes had been transformed in the soils under long-term field conditions, unlike the situation
225 observed with fresh amendments (D and W). These results could be to explain by the greater TOC content observed in
226 the AD treatments than in the AW treatments (Table 2). In the present study, the highest SM sorption values were found
227 in the field-amended soils despite their having lower TOC contents (Table 2) than the laboratory-amended soils (Table
228 2 and 3). Hence, increased TOC content by itself does not necessarily led to a greater SM sorption. This finding is
229 further supported by the k_{foc} values which were lower for laboratory-amended soils than for field-amended soils (Table

230 3). This could be understood in terms of the soils' organic matter quality (Delgado-Moreno et al., 2007) due to the
231 interactions between SM and organic matter also depends on the quality of the material (Haberhauer et al., 2001). In
232 fact, k_{foc} was significantly and positively correlated with HI ($r=0.564$, $p<0.01$) and negatively with WSOC ($r=-0.398$,
233 $p<0.05$), confirming that the evolution and transformation of organic matter in the studied soils was also important for
234 SM adsorption. The calculated SM k_{foc} values (around 214 for all treatments) are coherent with the values given in the
235 EU review report (mean 226, range 110–369) (SANCO, 2004).

236 The values of hysteresis coefficients (H) in fresh-amended soils (D and W treatments) were significantly lower than in
237 those amended with composted W (CW treatments) or in the field (AD and AW treatments) (Table 3). Consequently,
238 the adsorbed SM could be easily desorbed in D- and W-amended soils if the amendments are not mature. In fact, H was
239 significantly and positively with HI ($r=0.384$, $p<0.05$) and negatively with WSOC ($r= -0.437$). Although the
240 correlations are statistically significant, they explain less than 20% of the variability, and therefore should be regarded
241 as minor factors. SM desorption was correlated negatively ($p<0.05$) with HA and HI ($r= -0.398$ and $r= -0.462$,
242 respectively), indicating the importance of the level of humification in the adsorption-desorption of SM. Similar results
243 have been reported previously in soils where these wastes were incorporated: for MCPA (López-Piñeiro et al., 2013b;
244 Peña et al., 2015) and for metribuzin (López-Piñeiro et al., 2013a; Peña et al., 2016). Also, Cañero et al. (2015)
245 indicated that SM sorption was more reversible in amended than original soils, although they considered only fresh W
246 as organic amendment.

247 **3.2. Dissipation studies**

248 The SM dissipation curves for both original and amended soils are shown in Fig. 1. The data for all the treatments fit
249 well to first-order kinetics with $R^2 \geq 0.827$ (Table 3). The SM half-lives ($t_{1/2}$) in the original soils (18.1-27.0 days) were
250 similar to those found in other studies which range from 11.1 to 28.0 days in different soil types (e.g., Shaner et al.,
251 2006; Wolejko et al., 2017). According to these $t_{1/2}$ values (Table 3), the SM dissipation rates in original soils followed
252 the trend of sandy loam soil (S2) < loam soil (S1) < sandy clay loam soil (S3). These dissipation rate differences could
253 be caused by the differences in pH, since this was highest in S3 and lowest in S2 (Table 2). The results agree with those
254 of Alletto et al. (2013) who observed that SM mineralization was heavily influenced by pH, indicating that a higher soil
255 pH can foster the growth of soil microbial activity and so the dissipation of SM (Wolejko et al., 2017). In fact, in our
256 study, $t_{1/2}$ was significantly ($p<0.01$) and negatively correlated with pH ($r= -0.826$) and DHA ($r= -0.618$).

257 Independently of the soils type, the application of fresh D or W in the laboratory (D and W treatments) substantially
258 reduced the SM dissipation (Fig. 1), and consequently caused significant increases in $t_{1/2}$, (Table 3). Usually, adsorption
259 is found to limit dissipation because it reduces the available herbicide concentration. For example, SM mineralization
260 rates are inversely correlated with the herbicide's adsorption (Bedmar et al., 2017; Cañero et al., 2015). The observed

261 increase in SM adsorption in the D- and W-amended soils could thus be the cause for its high persistence (Table 3).
262 However, the greatest k_f values were found in the field soils amended with both wastes (AD and AW treatments of the
263 S3 soil) (Table 3). Their half-lives ($t_{1/2}$ values of 20.1, 18.8, 15.3, and 18.8 days for S3AD5, S3AD10, S3AW5, and
264 S3AW10, respectively) were significantly shorter than those of the laboratory soils amended with D and W, and very
265 close to the value of the original soil (18.1 days in S3). In our soils therefore, SM adsorption can not explain the results
266 observed in the dissipation studies. Thus, although a correlation could have been expected between k_f and $t_{1/2}$, no such
267 significant relationship was found (the results of the correlation study were $r = -0.068$, $p > 0.05$).
268 Rodríguez-Cruz et al. (2012) found that high rate of herbicide degradation may be caused by increase in soil microbial
269 activity. In our study, the field amended soils showed the greatest initial DHA values (1.89, 2.17, 1.97, and 2.71 μg
270 INTF $\text{g}^{-1} \text{h}^{-1}$ in S3AD5, S3AD10, S3AW5, and S3AW10, respectively) (Table 2). Throughout the dissipation study,
271 DHA was on average about 1.27 and 1.73 times greater in the S3AD5 treatment than in S3 and S3D5, respectively and
272 1.42 and 1.48 times greater in S3AW5 than in S3 and S3W5, respectively. Therefore, the greater DHA observed in the
273 field-amended treatments with both wastes (AD and AW) could mainly explain the short persistence of SM.
274 However, although the activity of soil microbial can increase with increasing in organic carbon content of the soil
275 (Pose-Juan et al., 2015) the DHA values of D and W treatments (regardless of dosage) fell to even below those of
276 original soils (Table 2). Again throughout the dissipation study, DHA was on average about 2.77, 1.61, and 1.37 times
277 lower in S1D5, S2D5, and S3D5 than in the corresponding original soils S1, S2, and S3, respectively, and 3.09, 1.40,
278 and 1.04 times lower in S1W5, S2W5, and S3W5 than in the corresponding original soils S1, S2, and S3, respectively.
279 Thus, independently of the soil type, the greater SM $t_{1/2}$ values found in the D2.5, D5, W2.5, and W5 treatments, could
280 be caused to the inhibitory effect of these amendments on microbial activity (Sampedro et al., 2009). The observed
281 differences in DHA between laboratory and field-amended soils could be a reflection of a possible adaptation of the soil
282 microorganisms to the two wastes (D and W) after 9 years of field application and so it favours the SM biodegradation
283 (Cabrera et al., 2010).
284 In contrast with the trend observed for the laboratory fresh W-amended soils, the CW amendment significantly
285 shortened the SM half-life, regardless of the soil type. In particular, the application of CW at the higher rate (5%)
286 reduced $t_{1/2}$ from 23.9 days in the original S1 soil to 22.9 days, from 27.0 days in the original S2 soil to 18.5 days, and
287 from 18.1 days in the original S3 soil to 12.3 days (Table 3). This effect could be attributed to increased microbial
288 activity in the CW-amended soils. As can be seen by Fig. 1, the lines of DHA in soils amended with CW are far above
289 the corresponding line of the original soils. Considering all the incubation times together, the DHA was on average
290 1.21, 4.95, and 1.13 times greater in S1CW5, S2CW5, and S3CW5 than S1, S2, and S3, respectively and 3.73, 6.90, and
291 1.18 times greater in S1CW5, S2CW5, and S3CW5 than S1W5, S2W5, and S3W5, respectively. The different rates of
292 dissipation observed with CW and W agree with the water-soluble phenols (WSP) values of the two amendments (2.40

293 g kg⁻¹ and 7.30 g kg⁻¹ for CW and W, respectively), implying greater toxicity of W than of CW for soil microorganisms
294 (Piotrowska et al., 2011; Sampedro et al., 2009).

295 The low values of $t_{1/2}$ observed in the CW-amended soils and field D- and W-amended soils may be due to the fact that
296 the soil microorganisms are consuming the herbicide as a carbon and energy resource rather than the available organic
297 substrates (WSOC), which was significantly reduced in these treatments with greater HI (Table 2). Indeed, $t_{1/2}$ was
298 positively correlated ($p < 0.01$) with WSOC ($r = 0.558$) and negatively with HI ($r = -0.510$), indicative of the importance of
299 the level of organic matter humification for the dissipation of SM.

300 One of the findings of our dissipation study was the significant increase in DHA values after SM application (2 hours),
301 demonstrating that this product does not any toxicity risk to microorganisms at dose used (1.5 kg ha⁻¹). Similarly,
302 Wolejko et al. (2017) reported that, in two agricultural soils, the application of SM at doses of 1.2 and 1.5 kg ha⁻¹ may
303 have contributed to an increase in DHA values from the 2nd to the 28th days after the herbicide's application.

304 **3.3. Leaching studies**

305 Breakthrough cumulative curves from the original and amended soils are shown in Fig. 2. The amendments led to
306 retardation of SM breakthrough, independently of the amendment applied or the soil type. This situation is coherent
307 with the greater k_f values found in the amended soils (Table 3).

308 The total percentage of SM eluted for the original soils ranged from 51.9% to 54.1% of the initially applied dose (Table
309 3). While similar SM leaching losses were observed by Cañero et al. (2015) in a Mediterranean olive grove soil, López-
310 Piñeiro et al. (2014) recovered 12.4% of the applied SM in leachates, although in this case through undisturbed soil
311 columns.

312 For all soils studied, the amendments application had a significant influence ($p < 0.05$) on SM leaching losses, though the
313 magnitudes of those losses depended on the soil and waste type (Table 3, Fig. 2). In the particular case of the laboratory
314 fresh D-amended soils, the effect differed according to the dose rate. Whereas for 5% of D application, the SM leaching
315 losses were lower by factors of 1.20 in S1 and 1.36 in S3, for the 2.5% rate of D application the leaching losses were
316 even slightly greater than those of the original soils (Table 3). In contrast, the laboratory fresh W-amended soils showed
317 significantly reduced SM leaching losses relative to the original soils (by factors of 2.70, 2.37, and 1.53 for S1W5,
318 S2W5, and S3W5, respectively). The higher WSOC found with the use of D than with W could explain this difference,
319 because this material can act as co-transporter in leaching the herbicide (Peña et al., 2015). Thus, considering the 5%
320 dose rates, the WSOC content of the W5 treatments was 1.40, 1.49, and 1.63 times lower than that of the corresponding
321 D5 treatment in the S1, S2, and S3 soils, respectively.

322 The CW amendment significantly reduced the percentage of herbicide leached by greater factors than the fresh W
323 amendment (Table 3, Fig. 2). Thus, the percentages of herbicide in the leachates relative to the original soils were lower

324 by factors of 2.71, 3.36, and 2.62 for S1CW5, S2CW5, and S3CW5, respectively. The above findings seem to
325 demonstrate that the amendment's degree of maturity is even more important than its organic matter content with regard
326 to the leaching of SM. In fact, the amount of SM leached was correlated negatively with both TOC ($p<0.05$, $r= -0.393$)
327 and HA ($p<0.01$, $r= -0.541$).

328 The percentage of SM leached from the field amended soils was significantly less than from the original and laboratory-
329 amended soils, independently of the amendment applied (Table 3; Fig. 2). In coherence with the adsorption, the greatest
330 k_f and H values corresponded to the field-amended soils (Table 3). In fact, various authors have suggested that
331 adsorption-desorption processes are key factors in the transport and environmental fate of herbicides in soils (e.g., Cox
332 et al., 2001; Gianelli et al., 2014; Hiller et al., 2010). The percentage of SM leached was significantly ($p<0.01$) and
333 negatively correlated with k_f ($r= -0.757$) and H ($r= -0.544$), showing that adsorption and desorption processes were also
334 responsible for the leaching behaviour of SM.

335 In most cases, the application of either waste, independently of its degree of organic matter maturity, increased the
336 amount of SM extracted from the soil columns, suggesting that relatively fresh organic matter allows intra-organic
337 matter diffusion and absorption, thus preventing the compound from biodegradation (Table 3). Fig. 3 shows the
338 distribution of SM at the different depths of the soil columns once the study was finalized. The pattern of this
339 distribution differs markedly between the original and the amended soil columns. In the former, large amounts of
340 herbicide were recovered from the bottom layer (15-20 cm), but in the latter, the opposite was the case with the amounts
341 of SM declining with column depth. These results are consistent with those described above for the adsorption process.
342 Certainly, the amount of SM extracted was significantly ($p<0.01$) and positively correlated with k_f ($r=0.543$).

343 **3.4. Herbicidal activity**

344 Table 4 lists the germination percentages obtained in the bioassay study. Although the organic waste amendments
345 (independently of the type of waste and the degree of organic matter maturity) increased SM adsorption (Table 3), they
346 did not reduce the herbicide's efficacy. Indeed, the germination percentages were zero when SM was applied (Table 4).
347 Furthermore, the application of organic amendments did have a significant influence ($p<0.05$) on the germination of the
348 *Lolium perenne* L. seeds in the control pots without herbicide application. The magnitude of this influence depended on
349 the type of waste applied and its degree of organic matter maturity (Table 4). Relative to the original soils, the
350 germination percentages were lower in the laboratory D- and W-amended soils, especially with D (Table 4). Thus, for
351 5% D addition, the germination decreased by factors of 3.28 in S1, 18.5 in S2, and 3.09 in S3, and for 5% W addition,
352 these factors were 1.64 in S1, 2.31 in S2, and 1.08 in S3. For the CW-amended soils however, the germination
353 percentages were significantly greater than for the W-amended soils, and quite similar to the original soils,
354 independently of soil type. Various experiments performed with olive-mill by-products and wastes have linked their

355 phytotoxicity to phenols (Albuquerque et al., 2006; Pinho et al., 2017). The present results might therefore be
356 attributable to the different WSP contents of the wastes – 2.40 g kg⁻¹ in CW, 7.30 g kg⁻¹ in W, and 14.6 g kg⁻¹ in D.
357 In the field-amended soils, the repeated applications of D and W significantly increased the germination percentages. In
358 particular, compared to the original S3 soil, these increases were by factors of 1.21 and 1.08 for S3AD10 and S3AW10,
359 respectively, and, compared to S3D10 and S3W10 (laboratory-amended soils), they were by factors of 7.51 and 1.73 for
360 S3AD10 and S3AW10, respectively.

361 The seedling length results were similar (Fig. 4). The values for the field-amended soils (10.2 cm and 9.16 cm for
362 S3AD10 and S3AW10, respectively) were significantly greater than for the laboratory fresh-amendment soils (3.20 cm
363 and 7.24 cm for S3D10 and S3W10, respectively). The seedling lengths in the laboratory W- and D-amended soils
364 (especially the latter) were smaller than in the original soils, independently of soil type (Fig. 4). Thus, at the 5% dose
365 rate, these differences were by factors of 1.51 and 1.35 on average for the D and W treatments, respectively. Again
366 however, the case was different with CW as organic amendment (the CW5 treatments), for which the lengths were
367 similar to those of the original soils.

368 These findings therefore indicate that the phytotoxicity of the fresh olive mill wastes (D and W) reflected in the lower
369 germination percentages and shorter seedling lengths disappears with both the natural transformation under field
370 conditions (AD and AW treatments) and the composting process (CW treatments) (Asses et al., 2018).

371 **4. Conclusions**

372 The results found in this study have shown that application of olive mill wastes (D and W) as organic amendments to
373 Mediterranean agricultural soils greatly influences the behaviour of SM. However these effects depend on soil and
374 amendment type, dose rate of amendment, and above all, on the degree of maturity. Amendments with fresh (D and W),
375 composted (CW), and field-aged (AD and AW) olive mill wastes led to increased SM adsorption capacity, although
376 without reducing the herbicide's effectiveness. The application of SM at a dose rate of 1.5 kg ha⁻¹ was not toxic for the
377 soil microorganisms, as was shown by the greater values of DHA found after two hours herbicide application. However,
378 the addition of the organic amendments influenced the soils' microbial activity, and therefore the persistence of SM, but
379 the magnitude of the effect depended on the maturity of the amendment. Thus, the application of fresh wastes (D and
380 W) increased the persistence of SM in all soils, whereas the CW and the AD and AW amendments had the opposite
381 effect, reducing the persistence of herbicide due to increase in the soils' microbial activity. The application of olive mill
382 wastes (D and W) as organic amendments may be considered as a useful strategy in order to reduce the leaching of SM
383 in soils poor in organic matter, especially if those wastes have previously been aged in the soil or composted.
384 Furthermore, these types of wastes should be applied in preference to fresh type so as to ensure that there are no
385 phytotoxicity concerns.

634 The SM concentration was determined by high-performance liquid chromatography (HPLC) model Waters 600E using
635 a device equipped with a UV diode-array detector (model Waters 996) and a Nova-Pack column C18 (150 × 3.9 mm, 4
636 μm particle size). The injection volume was 25 μL, the flow rate 1 mL min⁻¹, and the column temperature 30°C. The
637 mobile phase was 50% distilled water and 50% acetonitrile. The wavelength used for detection was 204 nm. The SM
638 concentrations were quantified against a linear calibration curve of chromatographic peak area versus SM standards
639 (0.2–50 μM). The standards were prepared in the same medium as the samples – in CaCl₂ 0.01M for the adsorption-
640 desorption and leaching experiments, and in methanol for the dissipation experiment.

641 **Text S2.**

642 In the laboratory, the amendments were added to the unamended soils at 2.5 and 5% (w/w) by adding the corresponding
643 amount of amendment to a pre-weighed amount of soils and then mixing with a stainless steel spatula to homogenize
644 the mixtures. The mixtures were made manually for each sample and each study in order to be able to ensure their
645 correct proportion. In the case of the field conditions, the amendments were applied annually, spreading the waste on
646 the soil surface manually, followed by arable-level homogenization using a mould-board plough.

647 **Text S3.**

648 Soil samples (5 g) were treated with 10 mL of SM solution. The initial concentration of SM ranged between 5 and 50
649 μM in 0.01 M CaCl₂ and each concentration was replicated three times. Samples were equilibrated by shaking
650 mechanically at 20 ± 2 °C for 24 hours. Preliminary kinetic studies were carried out to determine the optimal
651 soil:solution ratio and the equilibrium time according to OECD guideline 106 (OECD, 2000). Equilibrium
652 concentrations in the supernatants were determined by HPLC. The amount of SM adsorbed (C_s) was calculated from the
653 difference between the initial (C_i) and equilibrium (C_e) solution concentrations. The measurements with control samples
654 containing only SM showed that there were no losses of SM due to dissipation, volatilization or adsorption onto the
655 surface of the tubes.

656 Following the adsorption experiment, the desorption of SM from the soils was measured by successive remove-refill
657 from the 50 μM initial concentration points. The 5 mL of supernatant removed for adsorption analysis was replaced
658 with 5 mL of 0.01 M CaCl₂. The samples were re-suspended, shaken for 24 hours, centrifuged and filtered, and the
659 equilibrium concentration in the supernatant was determined. This desorption procedure was repeated three times. All
660 treatments had three replicates. Preliminary studies indicated that no measurable degradation occurred during the
661 sorption-desorption period. The herbicide adsorption and desorption results were fitted by the Freundlich model, $C_s = k_f$
662 $C_e^{n_f}$, where C_s (μM kg⁻¹) is the amount of herbicide adsorbed at the equilibrium concentration C_e (μM L⁻¹), and k_f and n_f

663 are the Freundlich coefficients that characterize the relative adsorption capacity and the adsorption intensity,
664 respectively, of the herbicide. The organic carbon soil adsorption coefficient (k_{foc}) was calculated from the k_f values as
665 $k_{foc} = (k_f \times 100)/TOC\%$. Hysteresis coefficients (H), for the adsorption-desorption isotherms were calculated as $H = n_a/n_d$,
666 where n_a and n_d are the Freundlich constants obtained from the adsorption and desorption isotherms, respectively. The
667 desorption percentage was calculated as $\%D = ((C_{sa} - C_{sd})/C_{sa}) \times 100$, where C_{sa} is the amount of SM adsorbed in
668 adsorption process and C_{sd} is the amount of SM adsorbed in desorption process.

669 **Text S4.**

670 The dissipation of SM in original and amended soils was determined by incubation experiments in which 500 g of
671 original and amended soils samples were spiked with SM at a rate of 1.5 mg of active ingredient kg^{-1} soil. The moisture
672 content was adjusted to 40% field capacity, and then the samples were thoroughly mixed by passing them several times
673 through a 2 mm-sieve. Herbicide-treated soil samples were transferred to 1-L glass jars where they were incubated at
674 20 ± 2 °C for 103 days in the dark. The moisture content was maintained at a constant level throughout the experiment
675 by adding distilled water as necessary, followed by vigorous shaking using a sterilized spatula. The soils were sampled
676 periodically, and finally frozen until assay, 5 g of soil samples in triplicates were extracted with 10 mL of methanol for
677 24 hours, and the SM concentration in the extracts was determined by HPLC. Incubation data were fitted to first-order
678 herbicide dissipation kinetics: $\ln C = \ln C_0 - k \cdot t$, where C is the herbicide concentration at time t (days), C_0 is the
679 initial herbicide concentration, and k ($days^{-1}$) is the first-order dissipation constant. The half-live ($t_{1/2}$) was calculated as
680 $t_{1/2} = 0.693/k$.

681 **Text S5.**

682 Dehydrogenase activity (DHA) was determined in original and amended soil samples from the dissipation study by the
683 method of García et al. (1993). One gram of soil was incubated for 20 hours at 20 °C in the dark with 0.2 mL of 0.4% 2-
684 (p-Iodophenyl)-3(p-nitrophenyl)-5-phenyl tetrazoliumchloride (INT) as substrate. At the end of the incubation, the
685 iodonitrotetrazoliumformazan (INTF) produced was extracted with 10 mL of methanol and the absorbance measured at
686 490 nm.

687 **Text S6.**

688 Leaching experiments were carried out using disturbed-soil columns (30-cm length \times 5-cm i.d.) constructed of PVC. To
689 minimize losses of soil during the experiment, the top 5 cm of the columns was filled with sea sand and the bottom 5
690 cm with sea sand plus glass wool. The remaining 20 cm was hand-packed with original or amended air-dried soil. The
691 experiment was performed with triplicates of the original and amended soil samples. The soil columns were saturated
692 with 0.01 M $CaCl_2$, allowed one to drain for 24 hours, and then the amount of SM corresponding to an application rate
693 of 1.5 $kg\ ha^{-1}$ dissolved in water was applied to the top of the columns. Each day the columns were leached with 0.01 M

694 CaCl₂ at a rate of 50 mL day⁻¹ until no herbicide was detected in the leachates. Leachates containing the herbicide were
695 collected daily, filtered, and assayed by HPLC. At the end of the monitoring period, the columns were sectioned into
696 four depths (0–5 cm, 5–10 cm, 10–15 cm, and 15–20 cm), and SM extracted by shaking (24 hours at 20 °C) 5 g of soil
697 with 10 mL of methanol. The suspensions were centrifuged, filtered, and assayed by HPLC in order to determine the
698 residual amount of herbicide at the different depths of the soil column.
